Abstract

Background: Recent data have suggested that nonalcoholic fatty liver disease (NAFLD) can occur in normal-weight subjects. This study examined the association of body fat percentage (BF%) with NAFLD and its risk factors in normal-weight individuals.

Objectives: The present study aimed to explain the influence of body fat on the risk of NAFLD.

Methods: A total of 59 subjects with body mass index (BMI) within the range of 18.5 - 24.9 kg/m² were selected from referrals to two major university polyclinics in Shiraz, Iran, from April to June 2019. Fatty liver grade, anthropometric characteristics, body composition, and cardiometabolic risk factors were measured in this study.

Results: Waist circumference ($P = 0.012$), fat mass ($P < 0.001$), triglycerides (TG) ($P = 0.027$), very-low-density lipoprotein (VLDL) ($P = 0.007$), and TG/high-density lipoprotein cholesterol (HDL-C) ratio ($P = 0.003$) increased; however, skeletal muscle mass decreased ($P < 0.001$) across the tertiles of BF%. The average of fatty liver grade was similar in the first and second tertiles; nevertheless, the fatty liver grade of participants in the third tertile was significantly higher (1.3 ± 0.9 vs. 0.4 ± 0.7 ; $P = 0.005$). In ordinal regression analysis, BF% (1.13; 95% CI: 1.04 - 1.22; $P = 0.003$), BMI (1.95; 95% CI: 1.02 - 3.74; $P = 0.045$), VLDL (1.77; 95% CI: 1.00 - 3.12; $P = 0.049$), and TG/HDL-C ratio (2.21; 95% CI: 1.26 - 3.86; $P = 0.006$) had positive associations with NAFLD; nonetheless, HDL-C (0.33; 95% CI: 0.16 - 0.67; $P = 0.002$) and dietary cholesterol (0.97; 95% CI: 0.95 - 0.997; $P = 0.028$) had inverse associations with NAFLD after the adjustments for age, gender, BMI, and physical activity.

Conclusions: The results of this study suggested that within normal weight ranges, NAFLD occurs more frequently in individuals with higher BF%. In addition, BF% can be used as an important marker in NAFLD screening.

Keywords: Non-alcoholic Fatty Liver Disease, NAFLD, Body Composition, Body Fat, Fatty Liver Grade

1. Background

Nonalcoholic fatty liver disease (NAFLD) is increasingly becoming a public health concern worldwide (1). The global prevalence of NAFLD is 25.2%, with the highest (31.8%) and lowest (13.5%) prevalence in the Middle East and Africa, respectively. The NAFLD is caused by excessive fat accumulation in hepatocytes without an external cause, such as alcohol, hepatotoxic medications, or viral infections (1). The NAFLD is related to metabolic diseases, such as type 2 diabetes and cardiovascular diseases (2). The NAFLD has been accepted as the hepatic manifestation of metabolic syndrome, a bunch of metabolic disorders originating from overweight and obesity (3, 4).

The link between obesity and NAFLD has been well established (5). Obesity contributes to the initiation, progression, and development of NAFLD to more complicated

disease conditions, such as nonalcoholic steatohepatitis, cirrhosis, and liver cancer (5). However, recent studies have suggested that NAFLD also develops in lean subjects (6, 7). Even normal-weight subjects may develop the risk factors for NAFLD. The results of a meta-analysis revealed that lean individuals with NAFLD had higher plasma glucose and lipids, insulin resistance, blood pressure, and waist circumference compared to lean subjects without NAFLD (6). A prospective cohort showed that the risk of developing metabolic comorbidities in lean subjects with NAFLD is similar to that of non-lean subjects with NAFLD (7).

Lean subjects may have excess abdominal fat, and this can increase NAFLD risk (6). Excess adipose tissue, particularly in intra-abdominal areas, is supposed to contribute to metabolic comorbidities in NAFLD (8). Fat tissue functions as a source of free fatty acids and adipokines, both of which

are involved in insulin resistance which is one of the core components in the initiation of NAFLD (9). Therefore, this study intended to determine the association of body fat percentage (BF%) with NAFLD and its cardiometabolic risk factors in normal-weight individuals. This study examined fatty liver grade, body composition, and cardiometabolic risk factors in a group of subjects with normal body mass index (BMI).

2. Objectives

Therefore, this study was designed to explain the influence of body fat on the risk of NAFLD to use the results in predicting NAFLD in normal-weight individuals, thereby preventing disease progression to more severe stages

3. Methods

3.1. Study Design

This cross-sectional study was performed during April to June 2019. The sample size was determined at 53 with the assumption of hypothetical NAFLD in subjects with low and moderate versus high BF% of 20.4% and 63.9%, respectively (10) (a two-sided confidence level of 95%, power of 80%, and case to control ratio of 0.5). The patients were recalled via poster advertisements in university polyclinics and hospitals. Upon recruitment, the study protocol was explained, and written consent was obtained from all the participants. The trial was reviewed and approved by the Ethics Committee of Shiraz University of Medical Sciences, Fars, Iran (approval code: IR.SUMS.REC.1398.314). Moreover, the study was performed according to the guidelines of the 1964 Helsinki Declaration and its later amendments.

3.2. Participants

The participants were selected from referrals to two major university polyclinics in Shiraz, Iran. The inclusion criteria were healthy individuals with normal weight (BMI: 18.5 - 24.9 kg/m²), absence of metabolic diseases (e.g., diabetes, thyroid problems, and cardiovascular diseases), no history of hepatitis and other hepatic and gallbladder disorders, and no history of consuming alcohol or medications affecting the lipid profile, blood pressure, and glucose, or predisposition to fatty liver (e.g., valproic acid and methotrexate).

3.3. Liver Ultrasound

The fatty liver grade was assessed in the fasting state by liver ultrasound (Medison-Accuvix-V10). The degree of echogenicity, visualization of the diaphragm, borders of the liver vasculature, and visualization of the posterior portion of the right hepatic lobe were used to assess the severity of fatty liver (grades 1 to 3).

3.4. Anthropometric and Blood Pressure Measurements

Height was measured using a wall-fixed tape to the nearest 0.1 cm. Bodyweight was measured while participants were in light clothes to the nearest 0.1 kg using a digital scale (GlamorBS-801, Hitachi, China). Body composition indices, including BF%, fat mass, and muscle mass, were determined by a bioelectric impedance analyzer (BIA) (InBody, Biospace Co., South Korea). Basal metabolic rate (BMR) and waist circumference were estimated by the BIA device. With an interval of at least 5 min, blood pressure was measured twice in each visit using a digital monitor (Beurer BM 44, Beurer GmbH, Germany); the mean values were considered the patient final blood pressure. Physical activity was assessed by a validated International Physical Activity questionnaire (IPAQ). The IPAQ is considered a cost-effective method with good reliability and acceptable validity, designed as a seven-item questionnaire assessing the duration and frequency of vigorous, moderate, and walking activities of the past 7 days. Metabolic equivalent hours per day (MET-h per day) was defined as the unit to represent this measure. To obtain a continuous variable score from the IPAQ (MET minutes a week), walking would be considered to be 3.3 METs, moderate physical activity to be 4 METs, and vigorous physical activity to be 8 METs. (11).

3.5. Biochemical Assessments

After 12-h overnight fasting, the blood samples were collected from all the participants. The serum was separated immediately and stored at -70°C for later analysis. Fasting blood glucose, low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), triglycerides (TG), total cholesterol, alanine transaminase (ALT), and aspartate transaminase were determined using commercial kits (Pars Azmun, Tehran, Iran) and an auto-analyzer (BT1500, Biotechnica Instruments, Italy). Very-low-density lipoprotein (VLDL) was estimated by dividing TG by 5.

3.6. Dietary Intake Assessment

Dietary intake was assessed by a validated food frequency questionnaire (FFQ) with 160 food and drink items

(12). The FFQ contained commonly consumed foods by Iranians with standard serving sizes. The participants were asked to report the consumption of each food item on a daily, weekly, or monthly basis within the past year. Portion sizes were then converted to grams. For dietary analysis, the nutrient composition of the consumed foods was determined by the modified Nutritionist IV software (version 3.5.2).

3.7. Statistical Analysis

Data analysis was performed using SPSS software (version 21; IBM, Armonk, NY, USA). Data normality was checked using the Shapiro-Wilk test. Furthermore, the abnormally distributed data (i.e., all except for blood pressure, total cholesterol, body weight, and body fat) were log-transformed before analysis. The participants were categorized into three groups based on the gender-specific tertiles of BF%. Between the gender-specific tertiles of BF%, parameters were compared using analysis of covariance (ANCOVA) adjusted for age, gender, BMI, and physical activity. Similarly, data comparison between different grades of fatty liver (grade 0 [healthy subjects] and grades 1-3 of liver steatosis) was made using ANCOVA and age, gender, BMI, and physical activity as the covariates. Nutrient intake between the tertiles of BF% was compared by one-way analysis of variance. Ordinal regression was used to explore the association between BF% and fatty liver grade. Again, the adjustments were made with the addition of age, gender, BMI, and physical activity in the model. STATA software (version 12.0; StataCorp, USA) was used to carry out ordinal regression analysis. A P-value of less than 0.05 was considered statistically significant.

4. Results

The data of 59 subjects were collected in this study. Demographics, anthropometrics, blood lipids, liver enzymes, and fatty liver grades were compared between the gender-specific tertiles of BF% (Table 1). There was no difference in age, gender, height, weight, and BMI among the tertiles of BF%. However, waist circumference ($P = 0.012$) and fat mass ($P < 0.001$) significantly increased; nevertheless, skeletal muscle mass and BMR significantly decreased ($P < 0.001$) across the tertiles. The TG ($P = 0.027$), VLDL ($P = 0.007$), and TG/HDL-C ratio ($P = 0.003$) also showed a significant increase across the tertiles. Fasting blood glucose, total cholesterol, LDL-C, blood pressure, and liver enzymes did not differ between the tertiles of BF%. The average of

the fatty liver grade was similar in the first and second tertiles; nonetheless, the fatty liver grade of participants in the third tertile was significantly higher (1.3 ± 0.9 vs. 0.4 ± 0.7 ; $P = 0.005$).

The comparison of nutrient intake among BF% revealed that except for saturated fatty acids and cholesterol decreasing across BF% tertiles, no difference was observed in energy, macro-nutrients, and micro-nutrients between BF% tertiles (Table 2). Similar to BF% tertiles, fat mass ($P = 0.002$), TG ($P = 0.027$), VLDL ($P = 0.018$), and TG/HDL-C ratio ($P = 0.001$) increased across the classifications for fatty liver grades (i.e., grades 0 [healthy], 1, 2, and 3) (Table 3). On the other hand, HDL-C decreased across the categories ($P = 0.015$). After the adjustments for age, gender, BMI, and physical activity, the difference in TG and VLDL was no longer significant. However, the difference in fat mass, HDL-C, and TG/HDL-C ratio remained significant after controlling the aforementioned covariates. Systolic blood pressure also showed a significant difference, although no clear pattern was observed. The difference in BMI, waist circumference, fasting glucose, total cholesterol, LDL-C, and liver enzymes was not statistically significant.

Figure 1 depicts the percentage of subjects with no or different fatty liver grades in the tertiles of BF%. In the first and second BF% tertiles, the percentage of healthy individuals was relatively high; nevertheless, in the third tertile, there was a higher percentage of individuals with fatty liver grades 1 and 2.

Ordinal regression analysis revealed substantial associations between fatty liver grade and some of the previously examined risk factors. Body fat, BF%, BMI, serum TG, VLDL, and TG/HDL-C ratio had positive associations with NAFLD; nonetheless, serum HDL-C and dietary cholesterol intake had inverse associations (Table 4). After the adjustments for age, gender, BMI, and physical activity, significant associations remained for BF% (1.13; 95% CI: 1.04 - 1.22; $P = 0.003$), BMI (1.95; 95% CI: 1.02 - 3.74; $P = 0.045$), VLDL (1.77; 95% CI: 1.00 - 3.12; $P = 0.049$), HDL-C (0.33; 95% CI: 0.16 - 0.67; $P = 0.002$), TG/HDL-C ratio (2.21; 95% CI: 1.26 - 3.86; $P = 0.006$), and dietary cholesterol intake (0.97; 95% CI: 0.95 - 0.997; $P = 0.028$).

5. Discussion

The results of this study showed that although no significant difference was observed in the BMI of the participants between BF% tertiles, TG and VLDL increased; however, skeletal muscle mass and BMR decreased across the BF% tertiles. Fatty liver grade had a positive association

^aValues are expressed as mean ± SD or No. (%).

^bThe qualitative data were compared using analysis of covariance. Except for age and height data, age, gender, BMI, and physical activity were used as covariates (BMI was excluded for weight and BMI). The chi-square test was used for gender. All the data except for blood pressure, total cholesterol, body weight, and body fat had abnormal distribution and were log-transformed before entering the analysis.

^cMean and standard deviation were obtained by non-transformed data; however, P-values were obtained by log-transformed data.

with BMI, body fat content and percentage, VLDL, and TG/HDL-C ratio, and an inverse association with HDL-C and dietary cholesterol.

5.1. BMI and Body Fat

Although the participants had normal BMI, there was a significant association between BMI and fatty liver grade. Body fat also indicated such an association with fatty liver grade. The results of regression analysis confirmed that BMI had a stronger association with fatty liver grade than body fat (1.95 vs. 1.22). However, BMI and body fat have a synergistic association with fatty liver (13). In other words, each of BMI and body fat correlates with NAFLD; nevertheless, their associations with NAFLD become stronger if they occur concurrently.

Although BMI, waist circumference, and whole and visceral fat correlate with the incidence of fatty liver (10), visceral fat is considered the primary determinant of hepatic fat accumulation (14, 15). According to the results of a cross-sectional study, overweight subjects with central adiposity are at increased risk of NAFLD, compared to BMI-matched subjects with less central adiposity (16). Due to the vicinity of intra-abdominal adipose tissue to the liver, free fatty acids released from these areas are thought to have a critical role in fat deposition in hepatocytes (17). In contrast to visceral fat, subcutaneous fat has been associated with the regression of NAFLD (15). The BIA device does not specify fat masses accumulated in visceral or subcutaneous areas; nonetheless, the current study reported waist circumference as an indicator of visceral fat. There was no asso-

ciation between waist circumference and fatty liver grade, although there was a trend for a positive association in the unadjusted model of regression analysis.

5.2. Skeletal Muscle Mass

In this study, there was a reduction in skeletal muscle mass across BF% tertiles, indicating that the increase of fat mass accompanied muscle loss. However, the association between skeletal muscle loss and NAFLD was not significant, although there was a trend toward the presence of an inverse association; nevertheless, some previous studies have reported such a relationship. For instance, a cross-sectional study conducted by Shida et al. (18) reported a close link between decreased muscle mass coupled with increased visceral fat and NAFLD risk. Accordingly, Mizuno et al. (19) reported a decline of skeletal muscle from the early stages of NAFLD and an increase in skeletal muscle to fat mass ratio predictive of ALT reduction in patients with NAFLD. In the current study, there was also no association between liver transaminases and body composition measurements (the data not presented). The lack of an association between muscle mass and either NAFLD or transaminases in the present study might be due to the inclusion criteria for recruiting the participants as they were

healthy with normal transaminases; however, in the aforementioned studies, subjects were NAFLD patients with relatively high levels of transaminases.

5.3. VLDL-C and HDL-C

The results of this study showed that VLDL and, to a larger extent, TG/HDL-C ratio had associations with NAFLD; nevertheless, HDL-C had an inverse association. The NAFLD is associated with large and triglyceride-over enriched VLDL particles (20). Poulsen et al. (21) using a tracer technique showed that the kinetics of VLDL is changed in NAFLD as patients with NAFLD cannot suppress VLDL secretion to compensate for the increased hepatic fat content. However, the increase in hepatic VLDL-TG export is inadequate to normalize intrahepatic TG content (22). The results of previous studies are in line with the findings of the current study. For instance, extensive cross-sectional studies have observed an association between TG/HDL-C and NAFLD (23, 24). Similarly, a cohort study suggested that TG/HDL-C may predict the incidence of NAFLD (25).

The alteration of VLDL/TG and HDL-C occur in opposite directions. The overproduction of VLDL is the core event in lipoprotein changes during metabolic syndrome and NAFLD (26). Circulating cholesteryl ester transfer protein

^dThe qualitative data were compared using analysis of variance. The chi-square test was used for gender.

(CETP) exchanges TG of VLDL with cholesteryl ester of HDL particles, thereby decreasing HDL-C concentration (27). In this regard, patients with NAFLD have shown higher CETP activity, compared to individuals without NAFLD (20).

5.4. Strengths and Limitations

This has been the first study examining the association between NAFLD and body fat in normal-weight individuals. Additionally, an adjusted statistical analysis was performed to control the confounding variables. The small sample size was a drawback of the study, causing abnormality in data distribution. Accordingly, the log transformation was performed to correct this abnormality. Furthermore, ultrasound is not the gold standard technique

for the diagnosis of NAFLD, and the results need to be checked with more reliable methods, such as magnetic resonance imaging. This method was used due to budget constraints. Moreover, body composition results should be confirmed by more accurate techniques, such as dual X-ray absorptiometry, because the measurements of BIA can be affected by factors such as hydration status, environment temperature, and exercise.

5.5. Conclusions

The results of this study suggested that within normal weight ranges, NAFLD occurs more frequently in individuals with higher BMI and BF%. There was also a positive association between NAFLD with VLDL and TG/HDL-C ratio and

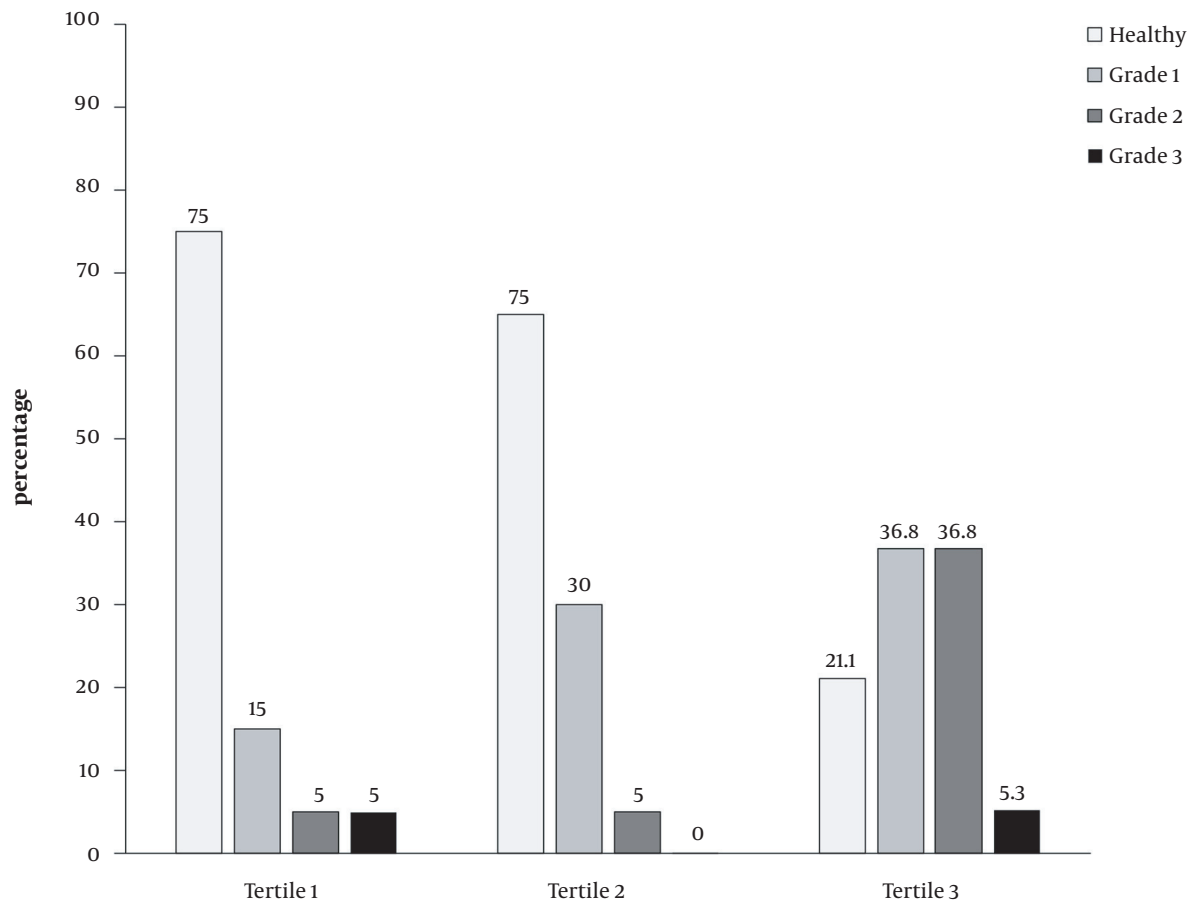

Figure 1. Percentage of patients with different grades of fatty liver in tertiles of body fat percentage; P-value assessed by chi-square reported as 0.008.

a negative association between NAFLD and HDL-C concentration. It is required to perform further studies to confirm these results with more accurate techniques for the diagnosis of NAFLD and assessment of body composition.

Acknowledgments

The results presented in this study were extracted from the thesis written by Ms Zeynab Hatami Zargaran.

Footnotes

Authors' Contribution: sStudy concept and design: Zeynab Hatamizargaran and Masoumeh Akhlaghi. Acquisition of the data: Zeynab Hatamizargaran. Analysis and interpretation of the data: Masoumeh Akhlaghi. Drafting of the manuscript: Masoumeh Akhlaghi and Zeynab

Hatamizargaran. Critical revision of the manuscript for important intellectual content and statistical analysis: Masoumeh Akhlaghi. Administrative, technical, and material support: Mohammadreza Sasani. Study supervision: Masoumeh Akhlaghi.

Conflict of Interests: The authors declare that there is no conflict of interest.

Ethical Approval: The trial was reviewed and approved by the Ethics Committee of Shiraz University of Medical Sciences (approval code: IR.SUMS.REC.1398.314). Moreover, this study was performed according to the guidelines of the 1964 Helsinki Declaration and its later amendments.

Funding/Support: The project was financially supported by Shiraz University of Medical Sciences, Fars, Iran (grant no.: 97-01-84-17890). The funder had no role in the study design, data collection and analysis, and manuscript preparation.

Table 4. Ordinal Regression Analysis of Associations Between Fatty Liver Grade and Several Cardiometabolic Risk Factors^a

	Unadjusted Model		Adjusted Model ^b	
	Odds Ratio	P-Value	Odds Ratio	P-Value
Body fat percentage	1.12 (1.05 - 1.21)	0.002	1.13 (1.04 - 1.22)	0.003
Body fat	1.23 (1.09 - 4.53)	0.001	1.22 (1.07 - 1.40)	0.003
Skeletal muscle mass	0.91 (0.54 - 1.54)	0.728	0.51 (0.26 - 1.02)	0.058
BMI	1.85 (1.07 - 3.19)	0.027	1.95 (1.02 - 3.74)	0.045
Waist circumference	1.76 (0.93 - 3.32)	0.084	1.33 (0.71 - 2.49)	0.368
Fasting blood glucose	1.23 (0.72 - 2.09)	0.456	1.48 (0.81 - 2.72)	0.205
Triglycerides	1.70 (1.05 - 2.76)	0.032	1.64 (0.95 - 2.84)	0.078
Total cholesterol	0.99 (0.97 - 1.01)	0.302	0.98 (0.96 - 1.01)	0.182
VLDL	1.77 (1.09 - 2.88)	0.021	1.77 (1.00 - 3.12)	0.049
LDL cholesterol	0.64 (0.36 - 1.13)	0.125	0.56 (0.29 - 1.08)	0.082
HDL cholesterol	0.42 (0.23 - 0.78)	0.006	0.33 (0.16 - 0.67)	0.002
Triglycerides/HDL cholesterol	2.31 (1.36 - 3.91)	0.002	2.21 (1.26 - 3.86)	0.006
Systolic blood pressure	0.97 (0.92 - 1.01)	0.164	0.95 (0.90 - 1.00)	0.054
Diastolic blood pressure	0.97 (0.92 - 1.03)	0.391	0.98 (0.92 - 1.04)	0.490
ALT	1.44 (0.91 - 2.30)	0.121	1.55 (0.94 - 2.55)	0.089
AST	1.54 (0.92 - 2.59)	0.101	1.35 (0.79 - 2.32)	0.271

Abbreviations: ALT, alanine transaminase; AST, aspartate transaminase; BMI, body mass index; HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

^aOdds ratios and P-values were obtained by log-transformed data.

^bAdjusted for age, gender, BMI, and physical activity; all the data except for blood pressure and body fat had abnormal distribution and were log-transformed before entering the analysis.

Informed Consent: Written consent was obtained from all the participants.
